

# Towards Wireless Security without Computational Assumptions

—Oblivious Transfer based on Wireless Channel Characteristics

Zhuo Hao, Sheng Zhong, *Member, IEEE*, Li Erran Li, *Member, IEEE*, Haifan Yao and Nenghai Yu, *Member, IEEE*

**Abstract**—Wireless security has been an active research area since the last decade. A lot of studies of wireless security use cryptographic tools, but traditional cryptographic tools are normally based on computational assumptions, which may turn out to be invalid in the future. Consequently, it is very desirable to build cryptographic tools that do not rely on computational assumptions.

In this paper, we focus on a crucial cryptographic tool, namely 1-out-of-2 oblivious transfer. This tool plays a central role in cryptography because we can build a cryptographic protocol for any polynomial-time computable function using this tool. We present a novel 1-out-of-2 oblivious transfer protocol based on wireless channel characteristics, which does not rely on any computational assumption. We also illustrate the potential broad applications of this protocol by giving two applications, one on private communications and another on privacy preserving password verification. We have fully implemented this protocol on wireless devices and conducted experiments in real environments to evaluate the protocol and its application to private communications. Our experimental results demonstrate that it has reasonable efficiency.

## I. INTRODUCTION

Wireless security has been an active research area since the last decade. A lot of studies of wireless security use cryptographic tools such as encryption, authentication, and key agreement in order to achieve security protection. These traditional cryptographic tools are very powerful, but most of them have a common weakness—normally, they are based on computational assumptions.

For example, consider one of the most frequently used cryptographic tools, symmetric key encryption. We have a number of very good existing encryption schemes, e.g., AES [1]. However, when we use AES to encrypt a message, we are actually making an implicit assumption: the AES block cipher is a pseudorandom permutation. Intuitively, this assumption implies that it is infeasible for an adversary to find the cleartext message from the ciphertext. Nevertheless, the above assumption of pseudorandomness is based on the cryptologists' understanding

of the *current* attacks on encryption schemes. It is possible that, in the future (maybe even in the near future), the AES scheme will be broken by newly invented cryptanalysis techniques.

In fact, there was a lesson a few years ago, when cryptologists broke several famous hash functions, including MD5 and SHA-0 [2], [3]. To be more precise, these hash functions had been assumed to be collision-resistant for more than ten years, but cryptologists found that these assumptions are invalid and there are quite efficient algorithms to find collisions of these hash functions. It is worth noting that the above discoveries were made after the hash functions became either national standards or de facto standards. Hence, it will be very desirable if we can remove cryptographic tools' dependence on such computational assumptions.

Of course, removing computational assumptions from the cryptographic tools, and thus from the wireless security systems, is a highly challenging problem. Consequently, in this paper, we do not intend to build a complete wireless security system that does not rely on computational assumptions. Instead, we would like to address a fundamental question as a crucial step towards solving this very challenging problem: Is it at all feasible to build wireless security systems without relying on computational assumptions?

Our answer to the above question is positive. Specifically, we propose that wireless security can be based on the physical channel characteristics rather than computational assumptions, as illustrated by a new type of protocols for key agreement in wireless networks [4], [5], [6], [7], [8], [9], [10].<sup>1</sup> In other words, the wireless channel characteristics can be used not only to achieve key agreement, but also to establish *any* cryptographic tool.

To be more precise, we use wireless channel characteristics to build a crucial cryptographic tool called 1-out-of-2 oblivious transfer. (For simplicity, hereafter we use OT to refer to oblivious transfer, and use  $OT_1^2$  to refer to 1-out-of-2 oblivious transfer.) The reason for choosing to work on  $OT_1^2$  is that it plays a central role in cryptography. In fact, Kilian [11] has proved that  $OT_1^2$  is “complete”, meaning that for any polynomial-time computable function, we can build a cryptographic protocol using  $OT_1^2$ . For example, electronic voting protocols, anonymous communications protocols, digital cash protocols, privacy preserving data mining protocols, etc.

<sup>1</sup>This is not the only way to do cryptographic operations without computational assumptions; quantum communications do not rely on computational assumptions as well. But quantum communications are out of the scope of this paper.

can all be built using  $OT_1^2$ . Hence, once we get an  $OT_1^2$  protocol independent of computational assumptions, we can actually use it to establish other cryptographic protocols independent of computational assumptions.

However, it is not easy to construct an  $OT_1^2$  protocol based on wireless channel characteristics. The main idea underlying our work is to employ a novel technique from [12]. We point out that both our channel model and our  $OT_1^2$  protocol are significantly different from those of [12]. Consequently, our use of their technique is non-trivial.

To illustrate the potential wide applications of our work, we give a method of private communications based on our  $OT_1^2$  protocol. Just like traditional symmetric key encryption schemes, this method allows two wireless devices that have a common secret key to communicate with each other privately. Nevertheless, the security of this method depends on wireless channel characteristics, not on computational assumptions.

Another application of our  $OT_1^2$  protocol is privacy preserving password verification. Using the method we present, one wireless device can verify a password from another wireless device in such a way that the password is not revealed to either the former device or any eavesdropper.

In summary, we have the following contributions in this paper.

- We are the first to construct an  $OT_1^2$  protocol based on the physical characteristics of wireless channels. Our  $OT_1^2$  protocol does not rely on any computational assumptions. Given the completeness of  $OT_1^2$  proved by Kilian [11], our work can be considered a crucial step towards building strong wireless security systems without computational assumptions.
- Our  $OT_1^2$  protocol has wide potential applications. In particular, we have given a method of private communications and a method of privacy preserving password verification based on our own  $OT_1^2$  protocol.
- We have *completely* implemented our  $OT_1^2$  protocol on *real, mobile* wireless devices, and evaluated it through extensive experiments. We have also experimentally evaluated our private communications method. Our experimental results demonstrate that our  $OT_1^2$  protocol and its application to private communications both have reasonable efficiency.

The rest of this paper is organized as follows. In Section II, we present technical preliminaries. In Section III, we design and analyze our  $OT_1^2$  protocol. In Sections IV and V, we show the two applications of our  $OT_1^2$  protocol. The implementation and experiments are described in Section VI. After briefly reviewing related work in Section VII, we conclude in Section VIII.

## II. TECHNICAL PRELIMINARIES

Throughout this paper, we follow the formulation presented in [8], [13]. For completeness, we briefly review the model of wireless channels and the quantization method in [8] and refer readers to [8] for more details. After that, we specify

the requirements that an  $OT_1^2$  protocol needs to satisfy and the security model we use to analyze  $OT_1^2$  and its applications.

**Model of Wireless Channel** Consider two parties  $A$  and  $B$ , and the wireless channel between them. Just like in [8], for ease of presentation, let  $h$  be the magnitude of the in-phase component of the Rayleigh fading process, which follows a Gaussian distribution. (Note that our protocol and analysis do not rely on this assumption of distribution. In fact, they can be easily extended to the general case; but the extension is notationally complex and less easy to understand.) Clearly,  $h$  can be viewed as a stochastic process; we use  $h(t)$  to represent the value of  $h$  at time  $t$ .

$A$  and  $B$  do not know the precise values of  $h(t)$ ; they can only make estimates. Specifically, let  $s(t)$  be a well known probe signal. Suppose that  $B$  sends a probe signal and  $A$  receives it at time  $t_1$ ;  $A$  sends a probe signal and  $B$  receives it at time  $t_2$ . Then  $A$  and  $B$  can estimate the channel respectively, using their received signals. In this case, the signals  $A$  and  $B$  receive can be expressed as follows:

$$r_a(t_1) = h(t_1)s(t_1) + n_a(t_1), \quad (1)$$

$$r_b(t_2) = h(t_2)s(t_2) + n_b(t_2), \quad (2)$$

where  $n_a(t_1)$  and  $n_b(t_2)$  are the receiver noises at  $A$  and  $B$ .

By using existing techniques of channel estimation, e.g., [14],  $A$  (resp.,  $B$ ) can obtain an estimate  $\hat{h}_a(t_1)$  (resp.,  $\hat{h}_b(t_2)$ ) from  $r_a(t_1)$  (resp.,  $r_b(t_2)$ ). These estimates satisfy the following equations:

$$\hat{h}_a(t_1) = h(t_1) + z_a(t_1), \quad (3)$$

$$\hat{h}_b(t_2) = h(t_2) + z_b(t_2), \quad (4)$$

where  $z_a(t_1)$  (resp.,  $z_b(t_2)$ ) represents the noise and interferences caused by  $n_a(t_1)$  (resp.,  $n_b(t_2)$ ) during the process of channel estimation.

By the channel reciprocity<sup>2</sup>, we can guarantee that  $h(t_1)$  and  $h(t_2)$  are correlated, if  $t_2 - t_1$  is small in the above probe and estimation process. More precisely, we need that the pair of probe signals exchanged by  $A$  and  $B$  are within the *coherence time* [15], [8] of the wireless channel. Here the coherence time  $T_C$  is typically inversely proportional to the maximum Doppler frequency  $f_m$  [15], [8]:

$$T_C \approx \frac{1}{f_m} = \frac{\lambda}{v}. \quad (5)$$

In equation (5),  $\lambda$  is the wavelength of the carrier signal, and  $v$  is the maximum moving speed of objects in the environment.

Note that the above description refers to the exchange of one single pair of probe signals. As we will see, our  $OT_1^2$  protocol actually requires exchanges of multiple pairs of probe signals. Unlike the short time interval between the two probe signals in the same pair, the time interval between any two different pairs of probe signals is chosen to be larger than the coherence time. In this way, the channel estimates derived from different

<sup>2</sup>If the involved wireless devices are not calibrated, methods similar to [8] can be used to reduce the problem introduced by the lack of calibration.

pairs of probe signals can be seen as independent from each other.

**Method of Quantization** When  $A$  and  $B$  have obtained their estimates  $\hat{h}_a$  and  $\hat{h}_b$ , respectively, they quantize these channel estimates into bit strings using a quantization function  $Q$ . The function  $Q$  is defined as follows:

$$Q(x) = \begin{cases} 1 & \text{if } x > q_+ \\ 0 & \text{if } x < q_- \end{cases} \quad (6)$$

where  $q_+$  and  $q_-$  are derived from the mean and standard deviation of channel estimates. Denote the mean by  $\mu$  and the standard deviation by  $\sigma$ . Let  $\alpha$  ( $\alpha > 0$ ) be a system parameter. We have

$$q_{+,-} = \mu \pm \alpha \cdot \sigma. \quad (7)$$

**Requirements for  $OT_1^2$  and Security Model** Our main objective in this paper is to build an  $OT_1^2$  protocol between  $A$  and  $B$ . In Section III, we describe how to build this protocol, including how to use the method of quantization mentioned above. Before we build the  $OT_1^2$  protocol, we need to first list the requirements for  $OT_1^2$ .

Assume that  $A$  has two bits  $b_0$  and  $b_1$  as her input, and that  $B$  has a bit  $s$  as his input. The requirements of an  $OT_1^2$  protocol is that, when the protocol terminates,

- 1)  $B$  gets the bit  $b_s$ ;
- 2)  $B$  gets no information about  $b_{1-s}$ ;
- 3)  $A$  gets no information about  $s$ .

Throughout this paper, we analyze the security of  $OT_1^2$  and its applications in the semi-honest model, which is one of the standard security models [16]. In this model, each involved party follows the protocol, but they may be curious in learning private information that they are not supposed to learn. Furthermore, eavesdropping by outsiders (i.e., parties not supposed to participate in the protocol) are allowed in our model.

### III. $OT_1^2$ BASED ON WIRELESS CHANNEL CHARACTERISTICS

Using the probing, estimation, and quantization process described in Section II, now we design an  $OT_1^2$  protocol and analyze it.

#### A. The $OT_1^2$ Protocol

Our  $OT_1^2$  protocol consists of two stages. In the first stage, the two parties send multiple probe signals to each other alternately, estimate the channel, and convert the estimates into bits, using the quantization method described in Section II. (Recall that the time interval between each pair of probe signals is within the coherence time, but the time interval between any two different pairs of probe signals is more than the coherence time.) The two parties terminate the first stage as soon as each of them has obtained at least  $N$  bits, where  $N$  is an even number and a system parameter, with a typical value of 100~200.

The main idea of the second stage is that  $A$  can xor her two secret bits with two sequences of masks respectively and then send the results to  $B$ . In order to guarantee that  $B$  gets only  $b_s$  but not  $b_{1-s}$ , we only need to make sure that the sequence of masks for  $b_s$  is known to  $B$ , but the other sequence is unknown to  $B$ . To achieve this objective, we have the following crucial observation:<sup>3</sup> Consider two pairs of probe signals such that  $A$  extracts the same bit from them using the quantization method in Section II. From these two pairs of probe signals, if  $B$  also extracts the same bit, then it is very likely that the bit extracted by  $A$  is equal to the bit extracted by  $B$ . In contrast, if from the two pairs of probe signals  $B$  extracts two different bits, then  $B$  has no idea about what bit is extracted by  $A$ . Consequently, for both sequences of masks, we let  $A$  use bits extracted from probe signals by  $A$  such that the next extracted bits are the same. In order to ensure the sequence of masks for  $b_s$  is known to  $B$ , we make sure that the masks for  $b_s$  correspond to those bits extracted by  $B$  that are identical to their next bits. In order to ensure the sequence of masks for  $b_{1-s}$  is unknown to  $B$ , we make sure that the masks for  $b_{1-s}$  correspond to those bits extracted by  $B$  that are not identical to their next bits.

More details of the second stage are given below.

Suppose that, at the end of the first stage,  $A$  has obtained  $N$  bits from the quantized channel estimates:  $\{BS_a(i)\}_{i=1,2,\dots,N}$ ;  $B$  has also obtained  $N$  bits from the quantized channel estimates:  $\{BS_b(i)\}_{i=1,2,\dots,N}$ . (Note that we use  $BS_a(i)$  to denote the  $i$ th term in the sequence  $BS_a$ . Similar notations are used throughout the paper.) The second stage can be divided into four steps.

**Step 1.**  $A$  generates an index sequence  $I$  by extracting all index  $i$  such that  $BS_a(2i-1) = BS_a(2i)$  ( $i \in [1, N/2]$ ).  $A$  sends  $I$  to  $B$  using a reliable communication protocol, e.g., TCP. Note that, throughout this  $OT_1^2$  protocol, communications using this reliable communication protocol need *not* to be encrypted.

**Step 2.** After  $B$  receives the index sequence  $I$  from  $A$ ,  $B$  generates two disjoint index sequences  $I_s$  and  $I_{1-s}$ , where  $I_s$  is subject to the following constraints:

- (1)  $|I_s| = n$  ( $n$  is a security parameter, with a typical value of 10~30), i.e., there are exactly  $n$  indices in the sequence  $I_s$ ;
  - (2)  $I_s \subseteq I$ , i.e.,  $I_s$  is a subsequence of  $I$ ;
  - (3) for all  $i \in I_s$ ,  $BS_b(2i-1) = BS_b(2i)$ ;
- and  $I_{1-s}$  is subject to the following constraints:
- (1)  $|I_{1-s}| = n$ ;
  - (2)  $I_{1-s} \subseteq I$ ;
  - (3) for all  $i \in I_{1-s}$ ,  $BS_b(2i-1) \neq BS_b(2i)$ .

Then  $B$  sends the two index sequences  $I_0$  and  $I_1$  to  $A$ , using a reliable communication protocol.

**Step 3.** Once  $A$  receives  $I_0$  and  $I_1$  from  $B$ ,  $A$  generates two sequences  $L_0$  and  $L_1$  as follows: for each  $e \in \{0, 1\}$  and each  $j$  such that  $1 \leq j \leq n$ ,

$$L_e(j) = b_e \oplus BS_a(2 \cdot I_e(j)),$$

<sup>3</sup>This observation is valid under the condition that the time interval between the two pairs of probe signals is more than the coherence time. Recall this condition is satisfied by our  $OT_1^2$  protocol.

Then  $A$  sends  $L_0$  and  $L_1$  to  $B$  using a reliable communication protocol.

Step 4. After  $B$  receives the  $L_0$  and  $L_1$  from  $A$ ,  $B$  computes  $b'_s$  using the following formula:

$$b'_s = \text{majority}(\{L_s(j) \oplus BS_b(2 \cdot I_s(j)), j \in [1, n]\}).$$

Here  $b'_s$  is supposed to be equal to  $b_s$ , the value  $B$  needs to obtain. (In Section III-B, we prove there is a high probability that  $b'_s = b_s$ .)

A formal description of the second stage is shown in Algorithm 1.

---

**Algorithm 1: Second Stage of  $OT_1^2$  Protocol**

---

**Input:**  $\{BS_a(i)\}_{i=1,2,\dots,N}$  and  $\{BS_b(i)\}_{i=1,2,\dots,N}$   
 $A$ 's secret bits  $\{b_0, b_1\}$ ,  $B$ 's secret bit  $s$

**Output:**  $B$  outputs  $b'_s$  as an estimate of his chosen  $b_s$

```

A:
I ← empty sequence
foreach i ∈ [1, N/2] do
  if BS_a(2i - 1) = BS_a(2i) then
    | add i into I
  end
end
A sends I to B

```

```

B:
I_s ← empty sequence, I_{1-s} ← empty sequence
foreach i ∈ I do
  if BS_b(2i - 1) = BS_b(2i) and |I_s| < n then
    | add i into I_s
  end
  else if BS_b(2i - 1) ≠ BS_b(2i) and |I_{1-s}| < n then
    | add i into I_{1-s}
  end
  if |I_s| = n and |I_{1-s}| = n then
    | break
  end
end
B sends I_s and I_{1-s} to A

```

```

A:
L_0 ← empty sequence, L_1 ← empty sequence
foreach e ∈ {0, 1} do
  foreach j ∈ [1, n] do
    | L_e(j) = b_e ⊕ BS_a(2 · I_e(j))
  end
end
A sends L_0 and L_1 to B.

```

```

B:
b'_s = majority({L_s(j) ⊕ BS_b(2 · I_s(j)), j ∈ [1, n]}).

```

---

### B. Protocol Analysis

Below we present an analysis to show that the three requirements for  $OT_1^2$  are all satisfied by our protocol. The analysis is based on the semi-honest model and under the assumption that the eavesdropper is passive. We also assume that the eavesdropper is more than half a wavelength away from both

$A$  and  $B$  [6], [8], so that the fading channel he experiences is statistically independent from the fading channel between  $A$  and  $B$ .

**Theorem 1.** *Under the standard assumptions [4], [8], [17] that the stochastic process  $\mathbf{h}$  is stationary and that  $h(t)$  is a Gaussian random variable, when our  $OT_1^2$  protocol is finished, for any  $\epsilon > 0$ ,  $B$  gets  $b_s$  with probability  $1 - \epsilon$  as long as  $n \geq \frac{\ln(\frac{1}{\epsilon})}{2(q-\frac{1}{2})^2}$ , where for any  $i \in I_s$ ,  $\Pr[BS_b(2i - 1, 2i) = BS_a(2i - 1, 2i) | BS_a(2i) = BS_a(2i - 1)] = q > \frac{1}{2}$ .*

*Proof:* For any  $i \in I_s$ , denote by  $\mathbf{x}_1$  and  $\mathbf{x}_2$  two vectors of channel estimates corresponding to  $[BS_b(2i - 1), BS_a(2i - 1), BS_b(2i), BS_a(2i)]^T$  and  $[BS_a(2i - 1), BS_a(2i)]^T$ , respectively. Since  $\mathbf{h}$  is a stationary Gaussian process,  $\mathbf{x}_1$  and  $\mathbf{x}_2$  are both random vectors following multivariate Gaussian distributions. Now we consider the following probability. For each  $i \in I_s$ , we have:

$$\begin{aligned} & \Pr[BS_b(2i - 1, 2i) = \text{"11"} | BS_a(2i - 1, 2i) = \text{"11"}] \\ &= \frac{\Pr[BS_b(2i - 1, 2i) = \text{"11"}, BS_a(2i - 1, 2i) = \text{"11"}]}{\Pr[BS_a(2i - 1, 2i) = \text{"11"}]} \\ &= \left( \int_{q_+}^{+\infty} \int_{q_+}^{+\infty} \int_{q_+}^{+\infty} \int_{q_+}^{+\infty} \frac{1}{(2\pi)^2 |\text{Cov}_{4,4}(\mathbf{x}_1)|^{1/2}} \times \right. \\ & \quad \left. \exp\left\{-\frac{1}{2}(\mathbf{x}_1 - \boldsymbol{\mu}_1)^T \cdot \text{Cov}_{4,4}^{-1}(\mathbf{x}_1) \cdot (\mathbf{x}_1 - \boldsymbol{\mu}_1)\right\} d^{(4)}x \right) / \\ & \left( \int_{q_+}^{+\infty} \int_{q_+}^{+\infty} \frac{1}{(2\pi) |\text{Cov}_{2,2}(\mathbf{x}_2)|^{1/2}} \times \right. \\ & \quad \left. \exp\left\{-\frac{1}{2}(\mathbf{x}_2 - \boldsymbol{\mu}_2)^T \cdot \text{Cov}_{2,2}^{-1}(\mathbf{x}_2) \cdot (\mathbf{x}_2 - \boldsymbol{\mu}_2)\right\} d^{(2)}x \right) \end{aligned}$$

In the above equation,  $\boldsymbol{\mu}_1$  and  $\boldsymbol{\mu}_2$  are the expectation vectors of  $\mathbf{x}_1$  and  $\mathbf{x}_2$ ;  $\text{Cov}_{4,4}(\mathbf{x}_1)$  and  $\text{Cov}_{2,2}(\mathbf{x}_2)$  are the covariance matrices of random vectors  $\mathbf{x}_1$  and  $\mathbf{x}_2$ . Similarly,

$$\begin{aligned} & \Pr[BS_b(2i - 1, 2i) = \text{"00"} | BS_a(2i - 1, 2i) = \text{"00"}] \\ &= \left( \int_{-\infty}^{q_-} \int_{-\infty}^{q_-} \int_{-\infty}^{q_-} \int_{-\infty}^{q_-} \frac{1}{(2\pi)^2 |\text{Cov}_{4,4}(\mathbf{x}_1)|^{1/2}} \times \right. \\ & \quad \left. \exp\left\{-\frac{1}{2}(\mathbf{x}_1 - \boldsymbol{\mu}_1)^T \cdot \text{Cov}_{4,4}^{-1}(\mathbf{x}_1) \cdot (\mathbf{x}_1 - \boldsymbol{\mu}_1)\right\} d^{(4)}x \right) / \\ & \left( \int_{-\infty}^{q_-} \int_{-\infty}^{q_-} \frac{1}{(2\pi) |\text{Cov}_{2,2}(\mathbf{x}_2)|^{1/2}} \times \right. \\ & \quad \left. \exp\left\{-\frac{1}{2}(\mathbf{x}_2 - \boldsymbol{\mu}_2)^T \cdot \text{Cov}_{2,2}^{-1}(\mathbf{x}_2) \cdot (\mathbf{x}_2 - \boldsymbol{\mu}_2)\right\} d^{(2)}x \right) \end{aligned}$$

Since the underlying Gaussian process  $\mathbf{h}$  is stationary, the Gaussian distributions of both  $\mathbf{x}_1$  and  $\mathbf{x}_2$  are symmetric. And also note that  $q_+$  and  $q_-$  are symmetric with the mean as the center, so we can get the following equation:

$$\begin{aligned} & \Pr[BS_b(2i - 1, 2i) = \text{"00"} | BS_a(2i - 1, 2i) = \text{"00"}] \\ &= \Pr[BS_b(2i - 1, 2i) = \text{"11"} | BS_a(2i - 1, 2i) = \text{"11"}]. \end{aligned} \quad (8)$$

On the other hand, for each  $i \in I_s$ ,

$$\begin{aligned} & \Pr[BS_b(2i-1, 2i) = BS_a(2i-1, 2i) | BS_a(2i) = BS_a(2i-1)] \\ &= \Pr[BS_a(2i) = 1 | BS_a(2i) = BS_a(2i-1)] \times \\ & \quad \Pr[BS_b(2i-1, 2i) = "11" | BS_a(2i-1, 2i) = "11"] \\ &+ \Pr[BS_a(2i) = 0 | BS_a(2i) = BS_a(2i-1)] \times \\ & \quad \Pr[BS_b(2i-1, 2i) = "00" | BS_a(2i-1, 2i) = "00"]. \end{aligned} \quad (9)$$

By combining (8) and (9), we get that

$$\begin{aligned} & \Pr[BS_b(2i-1, 2i) = BS_a(2i-1, 2i) | BS_a(2i) = BS_a(2i-1)] \\ &= \Pr[BS_b(2i-1, 2i) = "11" | BS_a(2i-1, 2i) = "11"] \\ &= \Pr[BS_b(2i-1, 2i) = "00" | BS_a(2i-1, 2i) = "00"]. \end{aligned}$$

Recall  $\Pr[BS_b(2i-1, 2i) = BS_a(2i-1, 2i) | BS_a(2i) = BS_a(2i-1)] = q$  for any  $i \in I_s$ . From the way  $I_s$  is generated, we know that

$\forall i \in I_s, BS_a(2i) = BS_a(2i-1), BS_b(2i) = BS_b(2i-1)$ . So, for any  $i \in I_s$ ,  $\Pr[BS_b(2i) = BS_a(2i)] = q$ . We can rewrite it as  $\Pr[BS_a(2 \cdot I_s(j)) = BS_b(2 \cdot I_s(j))] = q$ , where  $j \in [1, n]$ . The probability that  $B$  gets  $b_s$  is

$$\begin{aligned} & \Pr[b_s = b'_s] \\ &= \Pr[b_s = \text{majority}(\{L_s(j) \oplus BS_b(2 \cdot I_s(j)), j \in [1, n]\})] \\ &= \Pr[b_s = \text{majority}(\{b_s \oplus BS_a(2 \cdot I_s(j)) \oplus BS_b(2 \cdot I_s(j)), \\ & \quad j \in [1, n]\})] \\ &= \Pr[|\{BS_a(2 \cdot I_s(j)) = BS_b(2 \cdot I_s(j)), j \in [1, n]\}| > \frac{n}{2}], \end{aligned}$$

Because the time interval between any two different pairs of probe signals are greater than the coherence time, the  $n$  events  $\{BS_a(2 \cdot I_s(j)) = BS_b(2 \cdot I_s(j))\}, j \in [1, n]$  are all independent. For each  $j \in [1, n]$ , define an indicator random variable

$$Ind_j = \begin{cases} 1, & \text{if } BS_a(2 \cdot I_s(j)) = BS_b(2 \cdot I_s(j)), \\ 0, & \text{if } BS_a(2 \cdot I_s(j)) \neq BS_b(2 \cdot I_s(j)). \end{cases}$$

Then  $Ind_1, Ind_2, \dots, Ind_n$  are a sequence of independent Bernoulli random variables [18] with parameter  $q$ . Let  $X(n, q) = |\{Ind_j = 1, j \in [1, n]\}|$ . Then  $X(n, q)$  is a random variable following the binomial distribution  $Binomial(n, q)$ . Therefore,

$$\begin{aligned} & \Pr[b_s = b'_s] \\ &= \Pr[|\{BS_a(2 \cdot I_s(j)) = BS_b(2 \cdot I_s(j)), j \in [1, n]\}| > \frac{n}{2}] \\ &= \Pr[|\{Ind_j = 1, j \in [1, n]\}| > \frac{n}{2}] = \Pr[X(n, q) > \frac{n}{2}] \\ &= \sum_{i=\lfloor \frac{n}{2} \rfloor + 1}^n \binom{n}{i} q^i (1-q)^{n-i} = 1 - \sum_{i=0}^{\lfloor \frac{n}{2} \rfloor} \binom{n}{i} q^i (1-q)^{n-i}. \end{aligned}$$

Using the Hoeffding inequality [19], we can bound the above probability as follows:

$$\begin{aligned} \Pr[b_s = b'_s] &= 1 - \sum_{i=0}^{\lfloor \frac{n}{2} \rfloor} \binom{n}{i} q^i (1-q)^{n-i} \\ &\geq 1 - \exp(-2 \cdot \frac{(nq - \frac{n}{2})^2}{n}) = 1 - \exp(-2n \cdot (q - \frac{1}{2})^2). \end{aligned}$$

Because  $q > \frac{1}{2}$ , we can always make  $\Pr[b_s = b'_s]$  sufficiently close to 1 by increasing  $n$ . In particular, if we want the

probability to be not less than  $1 - \epsilon$ , then we can only need to guarantee that  $n \geq \frac{\ln(\frac{1}{\epsilon})}{2(q - \frac{1}{2})^2}$ . ■

**Remark.** In Theorem 1 we have assumed  $q > \frac{1}{2}$ . We stress this is a realistic assumption because  $q$  can be controlled by adjusting  $\alpha$ .

**Theorem 2.** When our  $OT_1^2$  protocol is finished,  $B$  gets no information about  $b_{1-s}$ .

*Proof:* (Sketch) Let's consider the index sequence  $I_{1-s}$ . For each  $i \in I_{1-s}$ , we have that

$$\begin{aligned} & \Pr[BS_a(2i-1, 2i) = "00" | BS_b(2i-1, 2i) = "01"] \\ &= \frac{\Pr[BS_a(2i-1, 2i) = "00", BS_b(2i-1, 2i) = "01"]}{\Pr[BS_b(2i-1, 2i) = "01"]} \\ &= \left( \int_{-\infty}^{q-} \int_{-\infty}^{q-} \int_{q+}^{+\infty} \int_{-\infty}^{q-} \frac{1}{(2\pi)^2 |\text{Cov}_{4,4}(\mathbf{x}_1)|^{1/2}} \times \right. \\ & \quad \left. \exp\left\{-\frac{1}{2}(\mathbf{x}_1 - \boldsymbol{\mu}_1)^T \cdot \text{Cov}_{4,4}^{-1}(\mathbf{x}_1) \cdot (\mathbf{x}_1 - \boldsymbol{\mu}_1)\right\} d^{(4)}x \right) / \\ & \quad \Pr[BS_b(2i-1, 2i) = "01"] \end{aligned} \quad (10)$$

Using the symmetry property of Gaussian distribution, we get that

$$\begin{aligned} & \left( \int_{-\infty}^{q-} \int_{-\infty}^{q-} \int_{q+}^{+\infty} \int_{-\infty}^{q-} \frac{1}{(2\pi)^2 |\text{Cov}_{4,4}(\mathbf{x}_1)|^{1/2}} \times \right. \\ & \quad \left. \exp\left\{-\frac{1}{2}(\mathbf{x}_1 - \boldsymbol{\mu}_1)^T \cdot \text{Cov}_{4,4}^{-1}(\mathbf{x}_1) \cdot (\mathbf{x}_1 - \boldsymbol{\mu}_1)\right\} d^{(4)}x \right) / \\ & \quad \Pr[BS_b(2i-1, 2i) = "01"] \\ &= \left( \int_{-\infty}^{q-} \int_{q+}^{+\infty} \int_{q+}^{+\infty} \int_{q+}^{+\infty} \frac{1}{(2\pi)^2 |\text{Cov}_{4,4}(\mathbf{x}_1)|^{1/2}} \times \right. \\ & \quad \left. \exp\left\{-\frac{1}{2}(\mathbf{x}_1 - \boldsymbol{\mu}_1)^T \cdot \text{Cov}_{4,4}^{-1}(\mathbf{x}_1) \cdot (\mathbf{x}_1 - \boldsymbol{\mu}_1)\right\} d^{(4)}x \right) / \\ & \quad \Pr[BS_b(2i-1, 2i) = "01"] \\ &= \frac{\Pr[BS_a(2i-1, 2i) = "11", BS_b(2i-1, 2i) = "01"]}{\Pr[BS_b(2i-1, 2i) = "01"]}. \end{aligned}$$

So,

$$\begin{aligned} & \Pr[BS_a(2i-1, 2i) = "00" | BS_b(2i-1, 2i) = "01"] \\ &= \frac{\Pr[BS_a(2i-1, 2i) = "00", BS_b(2i-1, 2i) = "01"]}{\Pr[BS_b(2i-1, 2i) = "01"]} \\ &= \frac{\Pr[BS_a(2i-1, 2i) = "11", BS_b(2i-1, 2i) = "01"]}{\Pr[BS_b(2i-1, 2i) = "01"]} \end{aligned} \quad (11)$$

$$= \Pr[BS_a(2i-1, 2i) = "11" | BS_b(2i-1, 2i) = "01"].$$

Since for each  $i \in I_{1-s}$ ,

$$\begin{aligned} & \Pr[BS_a(2i-1, 2i) = "00" | BS_b(2i-1, 2i) = "01"] + \\ & \Pr[BS_a(2i-1, 2i) = "11" | BS_b(2i-1, 2i) = "01"] = 1 \end{aligned}$$

we have

$$\begin{aligned} & \Pr[BS_a(2i-1, 2i) = "00" | BS_b(2i-1, 2i) = "01"] = \\ & \Pr[BS_a(2i-1, 2i) = "11" | BS_b(2i-1, 2i) = "01"] = \frac{1}{2} \end{aligned}$$

Similarly, we can get that

$$\Pr[BS_a(2i-1, 2i) = \text{"00"} | BS_b(2i-1, 2i) = \text{"10"}] = \\ \Pr[BS_a(2i-1, 2i) = \text{"11"} | BS_b(2i-1, 2i) = \text{"10"}] = \frac{1}{2}$$

From the above analysis, we can see that  $B$  gets no information about  $b_{1-s}$  from  $L_{1-s}$ . ■

**Theorem 3.** *When our  $OT_1^2$  protocol is finished,  $A$  gets no information about  $s$ .*

*Proof:* (Sketch) First we observe that  $A$  does not know which bits in  $BS_b$  are different from the corresponding bits in  $BS_a$ . So it is easy to see that, for any  $i \in I_0 \cup I_1$ , whether  $i \in I_0$  or  $i \in I_1$  is independent from the distribution of  $BS_b(2i-1, 2i)$ . So when the protocol is finished,  $A$  gets no information about  $s$ . ■

The above theorems demonstrate the security guarantees of our  $OT_1^2$  protocol. Nevertheless, all these theorems are proved in the semi-honest model and under the assumption that the eavesdropper is passive. In practice, if the participants of  $OT_1^2$  can deviate from the protocol, or if there is an active adversary launching a man-in-the-middle attack, then our  $OT_1^2$  protocol needs to be modified and improved.

#### IV. APPLICATION I: PRIVATE COMMUNICATIONS

In this section, we develop a method based on our  $OT_1^2$  protocol that, assuming  $A$  and  $B$  both know a secret key  $K$ , allows  $A$  to send a confidential message to  $B$ . Our target here is similar to symmetric key encryption and decryption in traditional cryptography. More precisely, we have (at least) the following requirements for our private communications method:

- If both  $A$  and  $B$  use the same key, then  $B$  should get the message sent by  $A$ .
- If  $A$  and  $B$  use two different keys, then  $B$  does not get the message sent by  $A$ .
- Any eavesdropper gets no information about the message sent by  $A$ .

However, we stress that our method is only similar to, *not identical* to symmetric key encryption and decryption in traditional cryptography. The reason is that our communication model is completely different from that of traditional cryptography and so the security model is also different. For example, with our method, there is no ciphertext in the traditional sense. Hence, issues like chosen plaintext attack (which allows an adversary to see the ciphertexts for his chosen plaintexts) and chosen ciphertext attack are not considered for our method.

The idea underlying our method of private communications is very simple: Imagine that the keys used by  $A$  and  $B$  are of only one single bit, and the message to be sent is also a single bit. In this (unrealistic) situation,  $A$  can easily send the message to  $B$  by executing an  $OT_1^2$  with  $B$ . In this  $OT_1^2$ ,  $B$ 's secret bit is his key, and  $A$ 's secret bit  $b_K$  is set to her message, where  $K$  is  $A$ 's key. It is easy to verify that our requirements listed above are all satisfied.

Of course, in a realistic scenario, the keys and the message are much longer. So we need to extend the above idea to

multiple bits. Nevertheless, there is a pitfall that we must avoid: If we use a straightforward extension of the above idea (i.e., doing an  $OT_1^2$  for each bit of the key, assuming the key and the message are of equal length.), and if  $A$  and  $B$  use two different keys, then  $B$  may end up getting part of the message sent by  $A$ , each bit of which corresponding to a bit position at which the two keys agree. To avoid this pitfall, we let  $A$  hide her message using a random mask, and then the mask is sent from  $A$  to  $B$  using a number of  $OT_1^2$  sessions. Therefore, if  $A$  and  $B$  have different keys, the mask  $B$  receives will be different from what  $A$  sends at a number of bit positions (where the two keys differ). But when  $B$  attempts to recover the message using the wrong mask, the error in the recovered message will not remain at these bit positions; instead, it will be spreaded over the entire message.

It is worth noting that not all properties of our  $OT_1^2$  protocol are needed in the construction of our private communications method. In other words, our method of private communications can actually be simplified and optimized, from a practical point of view. We present it in the current form just to demonstrate the power of our  $OT_1^2$  protocol.

Below is our method of private communications.

Let  $p$  be a prime of length  $k$  (where  $k$  is a parameter) that is well known, i.e., everybody knows  $p$ . Suppose that  $A$  and  $B$  both know a key  $K$  that is of length  $k$ . Recall that the objective is to send a confidential message  $M$  from  $A$  to  $B$ . Without loss of generality, suppose  $M \in \mathbb{Z}_p$ . The method consists of three steps.

Step 1.  $A$  selects a mask  $D$  from  $[0, 2^k - 1]$  uniformly at random.<sup>4</sup> She then computes  $C = (D \cdot M) \bmod p$ , and sends  $C$  to  $B$ .

Step 2. Denote the  $j$ th bit of  $D$  by  $D_j$ , and the  $j$ th bit of  $K$  by  $K_j$ . For each  $j \in [1, k]$ , an  $OT_1^2$  is executed between  $A$  and  $B$ , where  $A$ 's two secret bits are  $b_{K_j} = D_j$  and  $b_{1-K_j} = 1 - D_j$ , and  $B$ 's secret bit is  $s = K_j$ .

Step 3. Once all the  $k$   $OT_1^2$  sessions are finished,  $B$  should have obtained all bits of  $D$ . Then  $B$  recovers  $M$  by computing  $M = (C \cdot D^{-1}) \bmod p$ .

The above private communications method is formally described in Algorithm 2.

#### V. APPLICATION II: PRIVACY PRESERVING PASSWORD VERIFICATION

Besides private communications, our  $OT_1^2$  protocol can also be applied to privacy preserving password verification. Today, password verification is still one of the major methods of user authentication. For example, in wireless LANs, many base stations authenticate users using their passwords at the beginning of sessions. However, it is clear that, when users send their passwords through wireless links, there is a risk that the passwords may be overheard by an adversary. Furthermore, an adversary may impersonate a base station or a password

<sup>4</sup>Ideally, the generation of random numbers in our protocol should not depend on computational assumptions. How to achieve this is out of the scope of this paper.

**Algorithm 2:** Private Communications Method**Data:**  $p, k, K; M \in Z_p$ .**Result:**  $B$  receives  $M$ .

$A$ :  
 Select  $D$  from  $[0, 2^k - 1]$  uniformly at random.  
 $C \leftarrow (D \cdot M) \bmod p$ .  
 Send  $C$  to  $B$ .  
**foreach**  $j \in [1, k]$  **do**  
   perform  $\text{OT}_1^2 [b_{K_j} = D_j, b_{1-K_j} = 1 - D_j; s = K_j]$  with  $B$ .  
**end**

$B$ :  
 $M = (C \cdot D^{-1}) \bmod p$

protected server to ask users for their passwords. Hence, it is important to consider the privacy protection of passwords when we use passwords for authentication.

In this section, we study privacy preserving password verification, which allows one wireless device to verify the password from another wireless device without the risk of revealing the password. More precisely, we have the following requirements when  $B$  verifies the password of  $A$ .

- If  $A$ 's password matches the corresponding password in  $B$ 's record, then  $B$  should accept.
- If  $A$ 's password does not match the corresponding password in  $B$ 's record, then  $B$  should reject.
- In any case,  $A$  learns nothing about the password in  $B$ 's record except whether it matches  $A$ 's password or not.
- In any case,  $B$  learns nothing about  $A$ 's password except whether it matches the corresponding password in  $B$ 's record or not.
- An eavesdropper should not learn anything about either  $A$ 's password or the password in  $B$ 's record.

In the above, the fourth requirement guarantees that, even if  $B$  is corrupted by an adversary,  $B$  will not be able to learn  $A$ 's password as long as  $B$  has not already known it. (Of course, a corrupted device  $B$  might launch a probe attack, by repeatedly requesting  $A$  to do password authentication. Nevertheless, this is easy to prevent if  $A$  is required to stop trying after a few number of times.) So the fourth and fifth requirements together give a strong privacy protection for  $A$ 's password. Similarly, the third and fifth requirements together give a strong privacy protection for the password in  $B$ 's record.

To achieve the above objective, our main idea is to let  $A$  generate  $l$  pairs of random numbers and then execute  $\text{OT}_1^2$  with  $B$ . After these  $\text{OT}_1^2$ ,  $B$  receives one out of each pair of random numbers. So in total,  $B$  receives a sequence of  $l$  random numbers. Clearly, there are altogether  $2^l$  such sequences, from which  $B$  choose to receive one. Among these  $2^l$  sequences, only one sequence satisfies a special property: The product of all random numbers in this sequence is congruent to 1 (with respect to a prime modulus  $p$ ).  $B$  will receive this special sequence through these  $\text{OT}_1^2$  if and only if  $A$ 's password matches the password in  $B$ 's record. Therefore, in order to verify  $A$ 's

password,  $B$  only need to verify that the received sequence satisfies the special property described above.

Below are the details of our privacy preserving method for password verification.

Just like in Application I, let  $p$  be a well-known prime of length  $k$ , where  $k$  is a parameter. Without loss of generality, suppose that each password is of length  $l$ , where  $l$  is another parameter. Let  $\text{Pass}$  be  $A$ 's password.

Step 1.  $A$  sends her user identity to  $B$ . Using this identity,  $B$  finds the corresponding password in  $B$ 's record. Suppose that what  $B$  finds is  $\text{Pass}'$ .

Step 2. Denote by  $\text{Pass}_i$  (resp.,  $\text{Pass}'_i$ ) the  $i$ th bit of  $\text{Pass}$  (resp.,  $\text{Pass}'$ ). For each  $i \in [1, l - 1]$ ,  $A$  picks two random numbers  $\beta_{0,i}, \beta_{1,i} \in Z_p$  independently and uniformly. Finally,  $A$  computes

$$\beta_{\text{Pass}_{\ell}, \ell} = \left( \prod_{i=1}^{l-1} \beta_{\text{Pass}_i, i} \right)^{-1} \pmod{p},$$

and picks  $\beta_{1-\text{Pass}_{\ell}, \ell} \in Z_p$  uniformly and independently.

Step 3. Denote by  $\beta_{0,i,j}$  (resp.,  $\beta_{1,i,j}$ ) the  $j$ th bit of  $\beta_{0,i}$  (resp.,  $\beta_{1,i}$ ). For each  $i \in [1, l]$  and each  $j \in [1, k]$ ,  $A$  and  $B$  execute an  $\text{OT}_1^2$ , where  $A$ 's two secret bits are  $\beta_{0,i,j}$  and  $\beta_{1,i,j}$ , and  $B$ 's secret bit is  $\text{Pass}'_i$ ; let  $\beta'_{i,j}$  be what  $B$  receives in the  $\text{OT}_1^2$ .

Step 4. For each  $i$ ,  $B$  puts together the  $k$  bits  $\beta'_{i,1}, \beta'_{i,2}, \dots, \beta'_{i,k}$  to get an integer  $\beta'_i$ . Then,  $B$  verifies that

$$\prod_{i=1}^l \beta'_i \equiv 1 \pmod{p}.$$

A formal description of the above privacy preserving method for password verification is given in Algorithm 3.

## VI. IMPLEMENTATION AND EVALUATIONS

We completely implement our  $\text{OT}_1^2$  protocol on two laptops, one with Intel Core2 CPU of 2.33GHz and 2.0 GB memory, the other with Intel Pentium M CPU of 2.13GHz and 1001.5 MB memory. Both laptops run the Ubuntu Linux 9.10 operating system and use Netgear WAG511 802.11abg wireless network cards. Both cards use ath5k [20] as drivers and are configured to operate in the 802.11a frequency band (specifically, the 5.745GHz frequency band). The transmission power is set to be 30dBm for both cards.

In order that the two laptops can communicate directly without any intermediate relays, we configure one laptop in the access point (AP) mode, and configure the other laptop in the station mode. ICMP echo request packets are sent from the station to the AP at a constant rate. Once the AP receives the packet, it sends an ICMP echo reply packet back to the station.

We create one monitor interface on each of the two laptops, so that we can use tcpdump [21] to capture the packets. By customizing the tcpdump filters, we capture only ICMP echo request packets on the AP side and only ICMP echo reply packets on the station side. The received signal strength (RSS) in the radiotap header [22] is extracted from each captured packet. Because the transmission power levels for both sides are identical, the extracted RSS is a coarse measurement of

**Data:** Pass, Pass',  $p$ ,  $k$ ,  $l$ .

**Result:** If Pass=Pass', then  $B$  accepts  $A$ 's authentication request; otherwise  $B$  rejects  $A$ 's authentication request.

```

A:
foreach  $i \in [1, l - 1]$  do
  | pick two random numbers  $\beta_{0,i}, \beta_{1,i} \in Z_p$  independently
  | and uniformly.
end
 $\beta_{\text{Pass}_\ell, \ell} \leftarrow (\prod_{i=1}^{l-1} \beta_{\text{Pass}_\ell, i})^{-1} \pmod{p}$ .
Pick  $\beta_{1-\text{Pass}_\ell, \ell} \in Z_p$  uniformly and independently.
foreach  $i \in [1, l]$  do
  | foreach  $j \in [1, k]$  do
  | | perform  $\text{OT}_1^2[\beta_{0,i,j}, \beta_{1,i,j}; \text{Pass}'_i]$  with  $B$ . (Denote the
  | | bit  $B$  receives by  $\beta'_{i,j}$ )
  | end
end

B:
foreach  $i \in [1, l]$  do
  | Combine  $\beta'_{i,1}, \beta'_{i,2}, \dots, \beta'_{i,k}$  to get  $\beta'_i$ 
end
if  $\prod_{i=1}^l \beta'_i \equiv 1 \pmod{p}$  then
  | accept  $A$ 's authentication request.
end
else
  | reject  $A$ 's authentication request.
end

```

---

the amplitude of wireless channel. (Ideally, rather than using RSS, our experiments should use raw physical layer complex channel impulse responses. However, in order to perform our experiments on *off-the-shelf* 802.11 network cards, we choose to use RSS, just like in [8], [9].) Each of the RSS measurement is quantized into one bit.

As pointed out in [8], [9], large-scale shadow fading can lead to long sequences of zeros and ones in the extracted bit strings. We use the adaptive quantization method [9] to mitigate this effect. Specifically, we divide all the RSS measurements into blocks and compute the quantization parameters (by equation (7)) for each block. We denote the size of each block by  $m$ , which is a configurable parameter.

We measure RSS profiles and the number of probings in three settings. In the first setting, the two laptops are stationary. In the second setting, the station moves at a low speed (1m/s). In the third setting, the station moves at a high speed (2m/s  $\sim$  9m/s). In all three settings, we measure RSS profiles and minimum numbers of channel probings needed for an  $\text{OT}_1^2$ . The results are presented in Sections VI-A, VI-B and VI-C, respectively.

Besides the above experiments on RSS and the minimum number of channel probings, we have also experimentally studied the efficiency of our  $\text{OT}_1^2$  protocol. The results are given in Section VI-D.

In addition, we have also implemented the private communications method based on our  $\text{OT}_1^2$  protocol. The evaluations of this application are presented in Section VI-E.

### A. $\text{OT}_1^2$ between Stationary Devices

In the first setting, we place the two laptops at fixed locations. Specifically, we place them on two tables in a library, and the distance between them is 15 meters. A number of people are walking in the library at speeds of 0.5–1m/s, which causes variations in the wireless channel between the AP and the station. This environment is illustrated in Fig. 1.

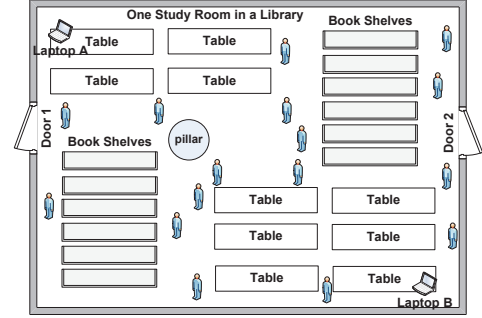

Fig. 1. The environment in the first setting.

In this setting, we first do an experiment to measure the RSS, which lasts for 300 seconds. During these 300 seconds, each laptop sends one probe signal every 100 milliseconds. From the captured packets, the RSS values are extracted and quantized into bit strings. Note that at both laptops we have implemented mechanisms to deal with packet losses and retransmissions, so that lost packets are removed from considerations and retransmitted packets are not repeatedly counted.

The extracted RSS sequences in the above experiment are shown in Fig. 2. Due to the channel reciprocity, the measured RSS profiles are mostly consistent. Inconsistencies exist because of receiver noises and interferences. We note that the absolute values of signal strengths have no influence on our  $\text{OT}_1^2$  protocol because we use the adaptive quantization method.

Fig. 2. Measured RSS profiles—the stationary setting.

Next, we do a number of experiments to measure the minimum number of channel probings required to achieve a certain error probability. (Here by error probability we mean the probability that the received bit in an  $\text{OT}_1^2$  is not equal to  $b_s$ .) We repeat our experiment for different error probabilities

between 0.01 and 0.0001, and for different combinations of quantization parameters  $m$  and  $\alpha$ . Fig. 3 shows our results. We can see that, to achieve an error probability of  $10^{-3}$ , we only need about 150 channel probings when  $m = 50$  and  $\alpha = 0.25$ .

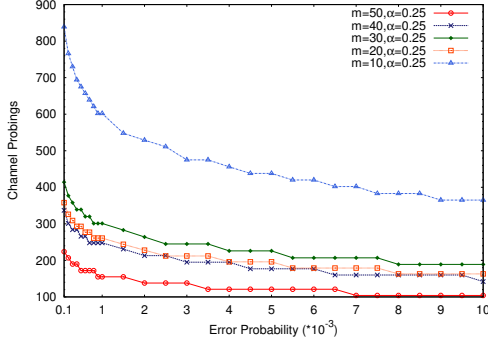

Fig. 3. The minimum channel probings to achieve required error probabilities—the stationary setting.

### B. $OT_1^2$ with Slowly Moving Station

In the second setting, we place the AP on a table, and let the station move at a speed of 1 m/s. The environment of this setting and the moving pattern of the station are shown in Fig. 4. The station moves along the arrowed path cyclically. Because the network cards are set to send and receive data in the 5.745GHz frequency band, we can calculate the approximate channel coherence time according to the following equation, in which  $c$  is the speed of light and  $f$  is the central transmission frequency.

Fig. 4. The environment in the second setting

$$T_C \approx \frac{\lambda}{v} = \frac{c}{f} = \frac{3 \cdot 10^8 \text{ m/s}}{5.745 \cdot 10^9 \text{ Hz}} \approx 52.219 \text{ ms}.$$

In this setting, we first do an experiment to measure the RSS, which lasts for about 160 seconds. During these 160 seconds, each laptop sends one probe signal every 53 milliseconds. From the captured packets, the RSS values are extracted and quantized into bit strings. The results are given in Fig. 5. We can see that due to the relative speed of 1 m/s, there are more major fluctuations of signal strengths than in the first setting.

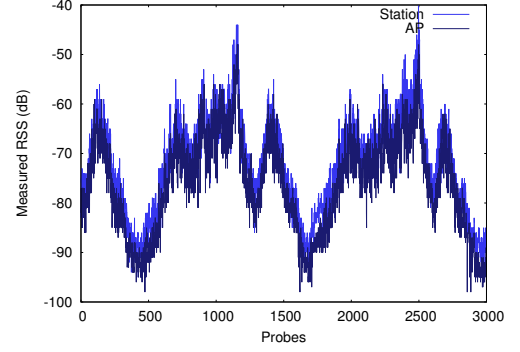

Fig. 5. Measured RSS profiles—the second setting.

Next, just like in the first setting, we do a number of experiments to measure the minimum number of channel probings required to achieve a certain error probability. We repeat our experiment for different error probabilities between 0.01 and 0.0001, and for different combinations of quantization parameters  $m$  and  $\alpha$ . Fig. 6 gives our results. We can see that, to achieve an error probability of  $10^{-3}$ , we only need about 100 channel probings when  $m = 50$  and  $\alpha = 0.2$ .

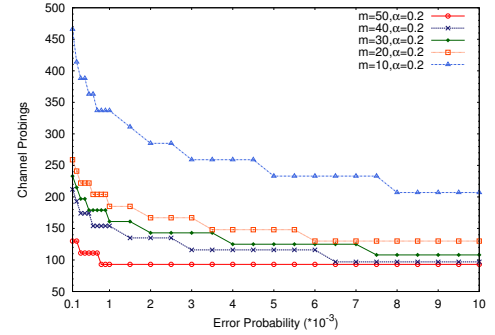

Fig. 6. The minimum channel probings to achieve required error probabilities – the second setting.

### C. $OT_1^2$ with High-Speed Moving Station

In the third setting, we do experiment in an empty ground. We place the AP on a car in the center of the ground, and drive another car surrounding the AP. The experiment environment is shown in Fig. 7.

When the relative speed is increased, the channel coherence time decreases, which makes it hard to keep ICMP echo request and reply in one coherence time. In order to solve this problem, we extract both the timestamp and the RSS from each message in the form of  $(timestamp, RSS)$  pair. For each such pair of the AP (denote it by  $(timestamp_1, RSS_1)$ ), we find  $(timestamp_2, RSS_2)$  from the measurements of the station satisfying  $|timestamp_1 - timestamp_2| \leq coherence\ time$  and treat  $(RSS_1, RSS_2)$  as the effective channel measurements from one channel probing. We use the ntpd tool [23] to keep the

Fig. 7. The environment in the third setting

system time synchronized at the two computers. Furthermore, when the relative speed increases, the small scale multi-path fading has more impact on channel variations. In order to keep the effects of small scale multi-path fading, we use the quantization parameter of a smaller  $m(m = 2)$  and  $\alpha = 0.1$ . And after that, we make a permutation to the bitstrings to increase the probability of “11”s and “00”s at  $A$ .

We do a number of experiments in which the relative speed is from 2m/s to 9m/s. At each relative speed,  $A$  and  $B$  measure RSS values and quantize them. The measured RSS values at these relative speeds are shown in Figs. 8~15, respectively. From Figs. 8~15, we can see that the channel fluctuations are more severe when the relative speed is high. However, the RSS measurements at  $A$  and  $B$  still have high degree of correlation.

Fig. 8. Measured RSS profiles at the relative speed of 2m/s.

We measure the minimum number of channel probings at different relative speeds in order to achieve 0.1% error probability. The results are shown in Fig. 16.

From Fig. 16 we can see that there is an increase of the minimum number of channel probings as the relative speed is increased. This is caused by two factors. Firstly, when the relative speed is increased, the number of lost packets also increases. Secondly, those  $(timestamp, RSS)$  pairs that cannot find a match are discarded from the final channel measurements. When the relative speed is larger, the channel coherence time becomes smaller, which decreases the matching probability

Fig. 9. Measured RSS profiles at the relative speed of 3m/s.

Fig. 10. Measured RSS profiles at the relative speed of 4m/s.

Fig. 13. Measured RSS profiles at the relative speed of 7m/s.

Fig. 14. Measured RSS profiles at the relative speed of 8m/s.

Fig. 15. Measured RSS profiles at the relative speed of 9m/s.

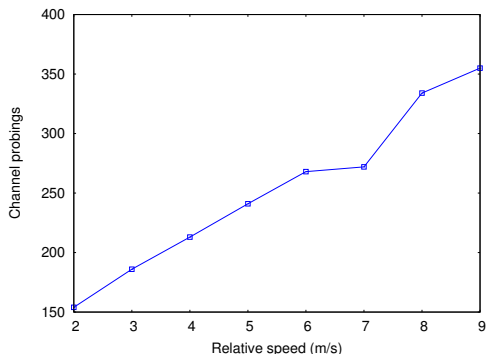

Fig. 16. The minimum channel probings at different relative speeds between AP and station.

of message timestamps. Nevertheless, the performance of the protocol becomes better when the speed is increased (see Fig. 17), because the time interval between two pairs of channel probings can be smaller.

#### D. Efficiency of $OT_1^2$

To test the efficiency of our  $OT_1^2$  protocol, we measure the running time at different relative speeds. At each relative speed, we run the  $OT_1^2$  protocol for 100 times and record the average running time. For the  $1m/s$  setting, each execution of the  $OT_1^2$  protocol includes 100 channel probings. For the high speed settings, we use at least the minimum number of channel probings shown in Fig. 16. The results are shown in Fig. 17.

From Fig. 17 we can see that our  $OT_1^2$  protocol can be completed within several seconds if one participant moves relatively to the other at a normal walking speed. When the relative speed is increased, the protocol execution time decreases very quickly. For example, at a typical city driving speed of 20.1 mph (9 m/s), the  $OT_1^2$  protocol can be finished within 2.5 seconds.

Fig. 17.  $OT_1^2$  protocol execution time at different relative speeds.

#### E. Evaluations of the Private Communications Method

We also implement the private communications method described in Section IV and evaluate it experimentally. Specifically, we choose  $k = 128$  and privately transmit a 128-bit message from the station to the AP. In this experiment, the random mask is set to have the same length as the message. We consider the transmission successful if the message can be completely recovered at the AP. At each tested speed, we try transmitting 50 messages in our experiment and all of them are successful.

The efficiency of our private communications method is illustrated in Fig. 18. From the results we can see that, as the relative speed is increased, the time for private communications is reduced. For example, if the relative speed is 9m/s, the total execution time is less than 300 seconds. We admit that this may not be as fast as private communications based on traditional cryptography. However, if the transmitted message is security critical, then we may want to consider sacrificing some efficiency in order to prevent possible privacy violation in the future (when the used cryptosystem is broken).

Fig. 18. Execution time of private communications method at different relative speeds.

## VII. RELATED WORK

As we have mentioned, our work is motivated by the previous works on key agreement using wireless channel characteristics. In [24], [25], it is shown that secure key agreement can be achieved using the correlated information between two wireless devices as long as they share an authenticated channel beforehand. In [26], Hershey et al. propose a key agreement protocol that extracts secret bits from phase differences of continuous waves. After that, many other methods [27], [28], [29], [4], [5], [6], [7], [8], [9], [10], [30] are proposed to enhance the security and/or improve the performance. In particular, Li et al. [4] propose a set of wireless security mechanisms, including wireless channel-based authentication, key extraction and key dissemination. In [6], Azimi et al. propose to achieve key agreement by quantizing the deep fading in mobile radio channels. The techniques of information reconciliation and privacy amplification [31] are used in their constructions.

Recently, Mathur et al. [8] propose a very practical method for secret key extraction from an unauthenticated wireless channel. They design a level crossing algorithm for achieving key agreement between the protocol participants. Their method is resistant to spoofing attack. To improve the secret bit rate efficiently, Jana et al. [9] design an adaptive and multi-bit quantization method for secret bit extraction. They do extensive experiments under a diversity of environments and make comparisons among them. In [10], a high rate uncorrelated bit extraction scheme is proposed, which further improves the efficiency by using fractional interpolation, de-correlation transformation and multi-bit adaptive quantization. Another recent work by Ye et al. [13] presents improvements in both efficiency and generality of channel state distributions.

While the aforementioned works are on key agreement, our work is on oblivious transfer (OT), or more precisely,  $OT_1^2$ . OT is a fundamental cryptographic tool that has been used in constructions of many complex cryptographic protocols. It is first proposed by Rabin [32]. Even, Goldreich and Lempel [33] propose  $OT_1^2$ , an important variant of OT. Crépeau [34] shows that  $OT_1^2$  is equivalent to the original version of OT proposed by Rabin. The importance of OT is reflected by its completeness [11], [35], [36], [37]. In his seminal work,

Kilian [11] shows that any general two-party cryptographic protocol can be built using OT. In [35], [36], [37], this result is extended to multiparty protocols.

In a theoretical work [12], Crépeau and Kilian propose an  $OT_1^2$  protocol based on noisy channels. Crépeau also proposes another  $OT_1^2$  protocol in a follow-up work [38] to increase the efficiency. The noisy channels they consider are simple discrete memoryless channels. In contrast, our  $OT_1^2$  protocol is based on wireless channels, which are much more realistic and complicated, having severe fluctuations with varying time and locations. Furthermore, in addition to theoretical analysis, we have fully implemented our  $OT_1^2$  protocols with off-the-shelf 802.11 network cards and carried out extensive experiments.

We have demonstrated one application of our  $OT_1^2$  protocol, private communications. In fact, there have been a number of works on private communications using the secrecy capacities of the wireless channel, e.g., [17], [39], [40], [41], [42], [43], among others. In particular, Vasudevan et al. [40] try to defend against the eavesdroppers by sending artificial noises to them, and focus on the scaling laws of secret communications without computational assumptions. In contrast, our private communications method is more practical in the sense that it does not need to control the received signals at the eavesdroppers. On the other hand, we stress that our private communications method is to illustrate the application of our  $OT_1^2$  protocol. We choose this application because it is simple and easy to understand, *not* because our private communications method is more efficient than the existing works on private communications.

## VIII. CONCLUSION

In this paper, we propose an  $OT_1^2$  protocol in the setting of a wireless network and give two applications of this protocol to illustrate its potential broad applications. The main advantage of our  $OT_1^2$  protocol is that it does not rely on any computational assumption. For security critical applications in wireless networks, such an advantage is of great importance, because as we have seen in the history, cryptographic tools based on computational assumptions may be broken after being used for years.

Although at this moment, our  $OT_1^2$  protocol is still not as fast as the traditional  $OT_1^2$  protocols based on computational assumptions, it has shown the feasibility of basing wireless security on physical channel characteristics, rather than on computational assumptions. Hence, our work can be considered a crucial step towards building wireless security systems that do not rely on computational assumptions.

In terms of security, our  $OT_1^2$  protocol and its applications are secure in the semi-honest model, and under the assumption that there is only a passive eavesdropper besides the protocol participants. We leave the consideration of fully malicious model and/or active man-in-the-middle attack to future work.
